Strong fields are comparable to the Schwinger field

$$E_{cr} = \frac{m_e^2 c^3}{e \hbar} \approx 1.3 \times 10^{18} \text{ V/m}$$

Quantified by the 'quantum parameter':

$$\chi_e = \frac{\gamma |\mathbf{E} + \mathbf{v} \times \mathbf{B}|}{E_{cr}}$$

Classical non-linearity parameter:

$$a_0 = \frac{e E_0}{m c \omega}$$

Strong fields arise in a range of environments

**B fields of up to 10^{11} T
around certain neutron
stars**

Effects of strong E
field are observable
close to nuclei with
 $Z > 80$

Predicted at the
interaction point of
future particle colliders

But they are hard to make in controlled experiments

Lasers? Highest powers provide $E_0 = 10^{14} \text{ V/m} \ll E_{cr} = 10^{18} \text{ V/m}$

BUT relativistic particles see
upshifted fields!

$$\chi_e = \frac{\gamma |\mathbf{E} + \mathbf{v} \times \mathbf{B}|}{E_{cr}}$$

**Tightly focused
PW-class laser**

$$\chi_e \sim 1$$

Laser wakefield acceleration (LWFA) creates GeV electrons

Gamma rays produced by non-linear Compton scattering

Non-linear Compton scattering:

Spectrum:

Synchrotron-like for given electron energy and laser intensity, e.g. shown for

$$a_0 = 5 \quad \gamma = 2000$$

Gamma rays produced by non-linear Compton scattering

Non-linear Compton scattering:

Angular distribution:

- Relativistically beamed to a few mrad along e^- direction
- Elliptical due to oscillation in linearly-polarised laser field

And e^-e^+ pairs produced by non-linear Breit-Wheeler

Non-linear Compton scattering:

Non-linear Breit-Wheeler:

- Exponentially suppressed for $\chi_e < 1$
- Energy ~ 100 s MeV

The ZEUS facility → a 2.5 PW + 0.5 PW system

- 2.5 PW LWFA driver allows access to up to ~ 5 GeV electrons
- 0.5 PW colliding beam focused tightly provides peak a_0 values ~ 50
- Together, $\chi_e \sim 1$ is achievable
- Still ramping up to above values - we had 1.5 PW + 0.2 PW

[Animated fly-through](#) of the laser!

Our set-up

- Observe non-linear Compton scattering via gamma spectrometer
- Observe non-linear Breit-Wheeler via positrons on Timepix3
- Observe radiation reaction via correlated changes to e^- spectra

LWFA results: broad spectrum e^- beams up to 2.3 GeV

5 shots chosen
randomly from
one run.

Collisions identified on gamma diagnostics

Collisions identified via gamma ray signals with:

- Low divergence
- High penetration into spectrometer

In this run of 105 shots, we estimate 33 successful collisions.
=> 31% hit rate.

Three of the brightest collisions

Three of the brightest collisions

Less elliptical profile
implies lower a_0

Three of the brightest collisions

Less elliptical profile
implies lower a_0

Also colliding with lower
electron energies

Three of the brightest collisions

Less elliptical profile
implies lower a_0

Earlier peak means lower photon energies -
consistent with lower a_0 and electron energies

Also colliding with lower
electron energies

Three of the brightest collisions

Earlier peak means lower photon energies -
consistent with lower a_0 and electron energies

Also colliding with lower
electron energies

Higher counts on gamma
diagnostics explained by higher
charge in electron beam

'Focusing' on one good shot - 17/09 run 7 shot 63

'Focusing' on one good shot - 17/09 run 7 shot 63

Using equations from [Fleck et al \(2024\)](#), we can use the elliptical shape to estimate the collision peak $a_0 \sim 5.3$ (but requires many assumptions).

'Focusing' on one good shot - 17/09 run 7 shot 63

By comparison to spectrometer response matrix, we can see that deposits peaking at layer 4 implies photons of energy ~ 25 MeV, but extracting full spectrum requires an assumption of shape.

Let's find consistent Monte-Carlo simulations

1. Ptarmigan - Monte-Carlo SFQED simulations for particle-laser collisions

Vary four unknowns: spatial and temporal offset of colliding beams, electron bunchlength, and peak a_0

Outputs: full gamma ray distribution

Ptarmigan: [Blackburn, King, Tang \(2023\)](#)

2. Topas - Monte-Carlo simulations of detector responses

OpenTOPAS:
[Faddegon et al \(2020\)](#),
[Shin et al \(2012\)](#)

3. Compare to experimental data and update estimates

In summary...

- ZEUS provides access to previously unexplored regimes of SFQED, via LWFA + colliding laser beam experiments
- Presented one such experiment with 30% collision rate, identified via low divergence, high energy gamma rays
- Quantitative analysis is difficult due to many unknown collision parameters => so proposed finding these by optimisation of a forward model
- Thanks for listening :)

Optimum parameters found by Bayesian optimisation

Experiment

a_0 : 2.59

Spatial offset : -48.3 μm

Temporal offset : -11.5 μm

Bunchlength : 2.65 μm *

Best simulation

* very low dependence

Resulting gamma ray distributions

$a_0 : 2.59$
